A systematic literature review of the Prisoner's Dilemma; collaboration and influence.

Nikoleta E. Glynatsi, Vincent A. Knight

Abstract

The Prisoner's Dilemma is a well known game used since the 1950's as a framework for studying the emergence of cooperation; a topic of continuing interest for mathematical, social, biological and ecological sciences. The iterated version of the game, the Iterated Prisoner's Dilemma, attracted attention in the 1980's after the publication of the "The Evolution of Cooperation" and has been a topic of pioneering research ever since.

The aim of this paper is to provide a systematic literature review on the Prisoner's Dilemma. This is achieved in two ways. Firstly, we review selected pieces of work and partition the literature timeline into five different sections with each reviewing a different aspect of it's research. Secondly, we analyse a comprehensive data set of articles on the Prisoner's Dilemma collected from five different prominent journals.

The questions answered in this manuscript are (1) what are the research trends in the field, (2) what are the already existing results within the field, (3) how collaborative is the field and (4) do authors influence the field more compared to other fields?

1 Introduction

Based on the Darwinian principle of survival of the fittest cooperative behaviour should not be favoured, however, cooperation is plentiful in nature. The golden paradigm of understanding the emergence of these behaviours is a particular two player non-cooperative game called the Prisoner's Dilemma (PD), originally described in [45].

In the PD each player has two choices, to either be selfless and cooperate or to be selfish and choose to defect. Each decision is made simultaneously and independently. The utility of each player is influenced by its own behaviour, and the behaviour of the opponent. Both players do better if they choose to cooperate than if both choose to defect. However, a player has the temptation to deviate as that player will receive a higher payoff than that of a mutual cooperation. Players' payoffs are generally represented by (1). Both players receive a reward for mutual cooperation, R, and a payoff P for mutual defection. A player that defects while the other cooperates receives a payoff of T, whereas the cooperator receives S. The dilemma exists due to constraints (2) and (3).

$$\begin{pmatrix} R & S \\ T & P \end{pmatrix} \tag{1}$$

$$T > R > P > S \tag{2}$$

$$2R > T + S \tag{3}$$

Another common representation of the payoff matrix is given by (4), where b is the benefit of the altruistic behaviour and c it's its cost (constraints (2) and (3) still hold).

$$\begin{pmatrix} b - c & c \\ b & 0 \end{pmatrix} \tag{4}$$

Constraints (2), (3) and rational behaviour guarantee that it never benefits a player to cooperate, indeed mutual defections is a Nash equilibrium. However, when the game is studied in a manner where prior outcome matters, defecting is no longer necessarily the dominant choice.

The repeated form of the game is called the Iterated Prisoner's Dilemma (IPD) and theoretical works have shown that cooperation can emerge once players interact repeatedly. Arguably, the most important of these works has been Robert Axelrod's "The Evolution of Cooperation" [26]. In his book Axelrod reports on a series of computer tournaments he organised. In these tournaments academics from several fields were invited to design computer strategies to compete. Axelrod's work showed that greedy strategies did very poorly in the long run whereas altruistic strategies did better. "The Evolution of Cooperation" is considered a milestone in the field but it is not the only one. On the contrary, the PD has attracted attention ever since the game's origins.

In Section 2 of this manuscript, a qualitative description of selected pieces of work will be presented. These have been separated into five sections, each reviewing a different aspect of research. The topics reviewed at each section are the following:

- Section 2.1, the **origins of the Prisoner's Dilemma**.
- Section 2.2, Axelrod's tournaments and intelligent design of strategies.
- Section 2.3, Evolutionary Dynamics
- Section 2.4, Structured strategies and training.
- Section 2.5, **Software**.

The aim of Section 2 is to provide a concrete summary of the existing literature on the PD. This is done to provide a review which will allow the research community to understand overall trends in the field, and already existing results.

In Section 3 a comprehensive data set of literature regarding the PD, and collected from the following sources, is presented and analysed. The data set has been archived and is available at [8].

- arXiv [77]; a repository of electronic preprints. It consists of scientific papers in the fields of mathematics, physics, astronomy, electrical engineering, computer science, quantitative biology, statistics, and quantitative finance, which all can be accessed online.
- PLOS [5]; a library of open access journals and other scientific literature under an open content license. It launched its first journal, PLOS Biology, in October 2003 and publishes seven journals, as of October 2015.
- IEEE Xplore Digital Library (IEEE) [57]; a research database for discovery and access to journal articles, conference proceedings, technical stan-

- dards, and related materials on computer science, electrical engineering and electronics, and allied fields. It contains material published mainly by the Institute of Electrical and Electronics Engineers and other partner publishers.
- Nature [49]; a British multidisciplinary scientific journal, first published on 4 November 1869. It was ranked the world's most cited scientific journal by the Science Edition of the 2010 Journal Citation Reports and is ascribed an impact factor of 40.137, making it one of the world's top academic journals.
- Springer [78]; a leading global scientific publisher of books and journals. It publishes close to 500 academic and professional society journals.

The aim of the analysis is to review the amount of published academic articles as well as to measure and explore the collaborations within the field.

2 Timeline

In this section literature regarding the PD is reviewed. The review starts from the formulation of the game and covers publications all the way to today.

2.1 Origins of the prisoner's dilemma

The origin of the PD goes back to the 1950s in early experiments conducted at RAND [45] to test the applicability of games described in [86]. The game received it's name later the same year. According to [114], Albert W. Tucker (the PhD supervisor of John Nash [85]), in an attempt to deliver the game with a story during a talk described the players as prisoners and the game has been known as the Prisoner's Dilemma ever since.

The early research on the PD had been very constrained. The only source of experimental results was through human subject research where pairs of participants simulated rounds of the game. Human subject research had disadvantages. Humans could behave randomly and in several experiments both the size and the background of the individuals were different, thus comparing results of two or more studies became difficult.

The main aim of these early research experiments had been to understand how conditions such as the gender of the participants [44, 72, 74], the physical distance between the participants [105], the effect of their opening moves [112] and even how the experimenter, by varying the tone of their voice and facial expressions [47], could influence the outcomes and subsequently the emergence of cooperation. An early figure that sought out to understand several of these conditions was the mathematical psychologist Professor Anatol Rapoport. The results of his work are summarised in [98], written alongside Albert M. Chammah.

Rapoport was also interested in conceptualising strategies that could promote international cooperation. Decades later he would submit the winning strategy Tit for Tat of the first computer tournament, run by Robert Axelrod. Though human subject research is used until today [113] they have largely been replaced by computer tournaments. In the next section these tournaments and several strategies that were designed by researchers, such as Rapoport, are introduced.

2.2 Axelrod's tournaments and intelligently designed strategies

As discussed in Section 2.1, before 1980 a great deal of research was done in the field, however, as described in [24], the political scientist Robert Axelrod believed that there was no clear answer to the question of how to avoid conflict, or even how an individual should play the game. Combining his interest in artificial intelligence and political science Axelrod created a framework for exploring these questions using computer tournaments. Axelrod asked researchers to design a strategy with the purpose of wining an IPD tournament. These strategies were constructed and not designed through an undirected process (such as in Section 2.4), and here they are refereed to as strategies of intelligent design. This section covers Axelrod's original tournaments as well as research that introduced new intelligently designed strategies.

Axelrod's tournaments made the study of cooperation of critical interest. As described in [99], "Axelrod's new approach has been extremely successful and immensely influential in casting light on the conflict between an individual and the collective rationality reflected in the choices of a population whose members are unknown and its size unspecified, thereby opening a new avenue of research". In a collaboration with a colleague, Douglas Dion, Axelrod in [25] summarized a number of works that were immediately inspired from the "Evolution of Cooperation" and in 2012, [60] wrote a review on IPD strategies and big competitions that had occurred since the originals.

The first reported computer tournament took place in 1980 [20]. A total of 13 strategies were submitted, written in the programming languages Fortran or Basic. Each competed in a 200 turn match against all 12 opponents, itself and a player that played randomly (called **Random**). This type of tournament is referred to as a round robin.

The tournament was run only once, each participant knew the exact length of the matches and had access to the full history of each match. Furthermore, Axelrod performed a preliminary tournament and the results were known to the participants. This preliminary tournament is mentioned in [20] but no details were given. The payoff values used for equation (1) where R = 3, P = 1, T = 5 and S = 0. These values are commonly used in the literature and unless specified will be the values used in the rest of the works described here.

The winner of the tournament was determined by the total average score and not by the number of matches won. The strategy that was announced the winner was the strategy submitted by Rapoport, **Tit For Tat**. The success of Tit for Tat came as a surprise. It was not only the simplest submitted strategy, it would always cooperates on the first round and then mimic the opponent's previous move, but it had also won the tournament even though it could never beat any player it was interacting with.

In order to further test the results Axelrod performed a second tournament in 1980 [21]. The second tournament received much more attention and had a total of 62 entries. The participants knew the results of the previous tournament and the rules were similar with only a few alterations. The tournament was repeated 5 times and the length of each match was not known to the participants. Axelrod intended to use a fixed probability (refereed to as 'shadow of the future' [25]) of the game ending on the next move. However, 5 different match lengths were selected for each match 63, 77, 151, 308 and 401, such that the average length would be around 200 turns.

Nine of the original participants competed again in the second tournament. Two strategies that remained the same were Tit For Tat and **Grudger**. Grudger is a strategy that will cooperate as long as the opponent does not defect, submitted by James W. Friedman. The name Grudger was give to the strategy in [69]. Though the strategy goes by many names in the literature such as, Spite [29], Grim Trigger [27] and Grim [116]. New entries in the second tournament included **Tit for Two Tats** submitted by John Maynard Smith and **KPavlovC**. KPavlovC, is also known as Simpleton [98], introduced by Rapoport or just Pavlov [90]. The strategy is based on the fundamental behavioural mechanism win-stay, lose-shift. Pavlov is heavily studied in the literature and similarly to Tit for Tat it's used in tournaments perform until today and has had many variants trying to build upon it's success, for example **PavlovD** and **Adaptive Pavlov** [68].

Despite the larger size of the second tournament none of the new entries managed to outperform the simpler designed strategy. The winner was once again Tit for Tat. Axelrod deduce that the performance of the strategy was due to:

- The strategy would start of by cooperating.
- It would forgive it's opponent after a defection.
- It would always be provoked by a defection no matter the history.
- It was simple.
- As soon as the opponents identified that they were playing Tit for Tat, they would choose to cooperate for the rest of the game.

The success of Tit for Tat, however, was not unquestionable.

Several papers showed that stochastic uncertainties severely undercut the effectiveness of reciprocating strategies and such stochastic uncertainties have to be expected in real life situations [80]. For example [83] proved that in an environment where **noise** (a probability that a player's move will be flipped) is introduced two strategies playing Tit for Tat receive the same average payoff as two Random players. Hammerstein [104], pointed out that if by mistake, one of two Tit for Tat players makes a wrong move, this locks the two opponents into a hopeless sequence of alternating defections and cooperations. The strategy does not fall short only in self interactions, [31] and [40] demonstrated that the strategy performed poorly in tournaments with noise as well. In [31, 118] the authors concluded that to overcome the noise error more generous strategies that Tit For Tat were needed. The introduced the strategies **Nice and Forgiving** and **OmegaTFT** respectively. A second type of stochastic uncertainty is misperception, where a player's action is made correctly but it's recorder incorrectly by the opponent. In 1986 [119]

introduced a strategy called **Contrite Tit for Tat** that was more successful than Tit for Tat in such environments. The difference between the strategies was that Contrite Tit for Tat was not so fast to retaliate a defection. The conclusions of all the aforementioned works show that there are at least two ways of coping with unintended defections that are due to happen in uncertain environments. Generosity and contrition. Generosity is letting a percentage of defections go unpunished and contrition, it's lowering a strategy's readiness to defect following an opponent's defection. These are properties not implemented within the basic reciprocity approach of Tit for Tat.

Several other works extended the reciprocity based approach which has led to new strategies that out perform Tit for Tat. For example Gradual [29]. Gradual was constructed to have the same qualities as those of Tit for Tat except one, their strategy **Gradual** had a memory of the game since the beginning of it. Gradual recorded the number of defections by the opponent and punished them with a growing number of defections. It would then enter a calming state in which it would cooperates for two rounds. In a tournament of 12 strategies, including both Tit for Tat and Pavlov, Gradual managed to outperformed them all. A strategy with the same intuition as Gradual is **Adaptive Tit for Tat** [115]. Adaptive Tit for Tat does keep a permanent count of past defections it maintains a continually updated estimate of the opponents behaviour, and uses this estimate to condition its future actions. In the exact same tournament as [29] with now 13 strategies Adaptive Tit for Tat ranked first. These results are some of many that illustrated the advantages of **memory** in the IPD games. Both these strategies are still of intelligent design. In Section 2.4 this topic will be discussed further with structured strategies.

The last family of intelligently designed strategies that are presented in this section are those of teams [38, 39, 101]. In 2004 Graham Kendall led the Anniversary Iterated Prisoner's Dilemma Tournament with a total of 223 entries. In this tournament participants were allowed to submit multiple strategies. A team from the University of Southampton submitted a total of 60 strategies [101]. All these were include strategies that have been been programmed with a recognition mechanism by default. Once the strategies recognise one another, one would act as leader and the other as a follower. The follower plays as a **Cooperator**, cooperates unconditionally and the leader would play as a **Defector** gaining the highest achievable score. The followers would defect unconditionally against other strategies to lower their score and help the leader. The result is that Southampton had the top three performers.

In this section the original computer tournaments and the origins of several intelligently designed strategies were covered. Axelrod's tournaments showed the advantages of reciprocal cooperation and simplicity in certain environments. Other works, also looked their limitations. The poor performance of reciprocal behaviour in noisy environments was highlighted by a number of works and finally, the design of teams and the notion of recognition patterns were discussed. The next section focuses on a different aspect of research which is evolutionary dynamics.

2.3 Evolutionary Dynamics

As yet, the emergence of cooperation has been discussed in the contexts of the one shot PD game and the IPD round robin tournaments. In the one shot game it is proven that cooperation fails, furthermore, in a series of influencing works Axelrod's demonstrated that reciprocal behaviour favours cooperation when individuals interact repeatedly. But does natural selection favours cooperation? Understanding the conditions under which natural selection can favour cooperative behaviour is important in understanding social behaviour amongst humans and other mammals [33].

Imagine a mix population of cooperators, C and defectors, D. The average payoff for defectors is always higher than cooperators. Under natural selection the frequency of defectors steadily increases until cooperators became extinct. Thus natural selection favours defection in the PD (Figure 1). However, there several evolutionary mechanisms that allow the emergence of cooperation. These mechanisms and papers which explore the PD in evolutionary settings are covered in this section.

In the later sections of [21], Axelrod discusses about an ecological tournament he performed using the 62 strategy of the second tournament to understand the reproductive success of Tit for Tat. In his ecological tournament the prevalence of each type of strategy in each round was determined by that strategy's success in the previous round. The competition in each round would become stronger as weaker performers were reduced and eliminated.

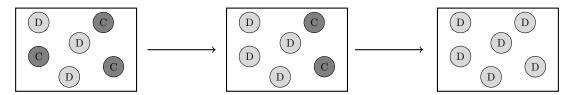

Figure 1: Natural selection favours defection in a mixed population of Cooperators and Defectors.

The ecological simulation concluded with a handful of nice strategies dominating the population whilst exploitative strategies had died off as weaker strategies were becoming extincted. This new result led Axelrod to study the IPD in an evolutionary context based on several of the approaches established by the biologist John M. Smith [109, 107, 108]. A fundamental figure within evolutionary game theory and a participant of Axelrod's second tournament. Axelrod and the biologist William Donald Hamilton wrote about the biological applications of the evolutionary dynamics of the iterated prisoner's dilemma [26] and won the Newcomb-Cleveland prize of the American Association for the Advancement of Science.

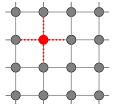

In Axelrod's model [22] pairs of individuals were paired from a population and played the IPD. The number of interactions between the pairs were not fixed, but there was a probability defined as the importance of the future of the game w, where 0 < w < 1, that the pair would interact again. For a sufficient high w [22] showed that Tit for Tat would become common. Note that Axelrod stated that Tit for Tat would be evolutionary stable (ESS), however, this results is inaccurate. In [22] he states that "Tit For Tat is a ESS if and only if it is invadable neither by a Defector nor the strategy which alternates defection and cooperation", which is not the definition of an ESS. Moreover, Boyd and Lorderbaum [33] proved that if w, the importance of the future of the game, is large enough then no deterministic strategy is ESS because it can always be invaded by any pair of other strategies. This was also independently proven by [96].

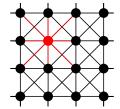

Thus no single mutant can do better than nice strategies in the IPD in evolutionary context, no cooperative strategy as long as it is deterministic can be ESS because it can always be invaded. These conclusions are all made in populations where individuals could interact with everyone in the population. Another approach is to consider constrained interactions were some sort of structure is applied to who individual can interact with who. This was originally formulated in 1992 by [73]. Nowak and May. They explored how local interaction alone can facilitate population wide cooperation in a one shot PD game.

The two deterministic strategies Defector and Cooperator, were placed onto a two dimensional square array where the individuals could interact only with the immediate neighbours. The number of immediate neighbours could be either, fourth, six or eight. As shown in Figure 2, where each node represents a player and the edges denote whether two players will interact. This topology is refereed to as spatial topology. Thus, each cell of the lattice is occupied by a Cooperator or a Defector. At each generation step each cell owner interacts with its immediate neighbours. The score of each player is calculated as the sum of all the scores the player achieved at each generation. At the start of the next generation, each lattice cell is occupied by the player with the highest score among the previous owner and the immediate neighbours.

Local interactions proved that as long as small clusters of cooperators form and they can benefit from interactions with other cooperators and while avoiding interactions with defectors, global cooperation will continue. Thus, local interactions proved that even for PD cooperation will be extinct.

Structured populations continue to prove the emergence of cooperation in natural selection. Whilst using the payoff matrix (4), [94] proved that as long as the benefit to cost ratio $\frac{b}{c}$ is higher to the number of neighbours, cooperation can evolve. In [76] it was shown that small world topology graphs favour cooperation. Moreover, [122] studied graphs were a probability of rewiring ones connections was in place, however, the rewire could be with any given node in the graphs and not just with imitate neighbours. Perc etc all showed that "making of new friends" may be an important activity for the successful evolution of cooperation, but also that partners must be selected carefully and one should keep their number limited.

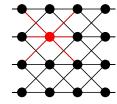

Figure 2: Spatial neighbourhoods

Finally, other mechanisms include reputation [58, 91, 111] and communication tokens [82] which are partner identification methods. Another related approach is using a tag based partner identification [34, 51, 82, 100]. Tags allow cooperative strategies to distinguish 'them' from the rest.

This section has focused on evolutionary dynamics and how different evolutionary settings can used to shed some light to how cooperation emerges in populations. In the following section evolutionary settings are used to train strategies.

2.4 Structured strategies and training

This section covers strategies opposite to that of intelligent designed discussed in Section 2.2. These are strategies that have been trained using generic strategy archetypes. For example, in [23] Axelrod decided to explore deterministic strategies that took into account the last 3 turns of the game. For each turn there are 4 possible outcomes (CC, CD, DC, DD), thus for 3 turns there are a total of $4 \times 4 \times 4 = 64$ possible combinations. Therefore, the strategy can be defined by a series of 64 C's/D's, corresponding to each history; a lookup table. A lookup table is a generic strategy archetype. This lookup table was then trained using a genetic algorithm. The outcome strategies of the training are referred here as structured strategies, and, several structured strategies are covered in this section.

In 1996 [81] considered finite state automata as an archetype, more specifically, Moore machines [84]. He used a genetic algorithm was used to train finite state machines this time, in environments with noise. Miller's results showed that even a small difference in noise (from 1% to 3%) significantly changed the characteristics of the evolving strategies. The strategies he introduced were **Punish Twice**, **Punish Once for Two Tats** and **Punish Twice** and **Wait**. In [19] finite state automata and genetic algorithm were also used for a series experiments. The size of the population varied between the experiments, however, there were two strategies frequently developed by the training process and more over they were developed only after the evolution had gone on for many generations. These were **Fortess3** and **Fortess4**.

Following Miller's work in 1996 [53] introduced the first structured strategies based on neural networks that had be trained using a genetic algorithm. Harrald and Fogel considered a single layered neural network which had 6 inputs. These were the last 3 moves of the player and the opponent, similar to [23]. Neural networks have broadly been used to train IPD strategies with genetic algorithms [18, 35, 75] and particle swarm optimization [46].

In a series of works [52] and [64] explored several of the aforementioned archetypes, and the two mentioned training methods; the genetic algorithm and the particle swarm algorithm. The archetypes used included lookerup tables, finite state machines, neural networks, hidden Markov models [42] and a Gambler. Hidden Markov models, are a stochastic variant of a finite state machine and Gamblers are stochastic variants of lookup tables.

The structured strategies that arised for the training were put up against a large number of strategies in two following settings:

- A Moran process, which is an evolutionary model of invasion and resistance across time during which high
 performing individuals are more likely to be replicated.
- A round robin tournament.

In a round robin tournament with over 200 strategies (the tournament was simulated using the and the strategies implemented within the software), [52] showed that the top spots were dominated by the trained strategies of all the archetypes. More specifically, the top three strategies had been **Evolved LookUp 2 2 2**, **Evolved HMM 5** and **Evolved FSM 16**.

The result of [64] showed that the trained strategies would overtake the population. More over, the strategies evolve an ability to recognise themselves by using a handshake. This characteristic of the strategies was an important one because in a Moran process this recognition mechanism allowed these strategies to resist invasion.

Throughout the different methods of training that have been discussed in this section, a spectrum of structured strategies can be returned. Differentiating between strategies is not always an easy task. It is not obvious looking at a finite state diagram how a machine will behave, and many different machines, or neural networks can represent the same strategy. For example Figure 3 shows two finite automata and both are a representation of Tit for Tat.

(a) Tit for Tat as a finite state machine with 1 state. (b) Tit for Tat as a finite state machine with 2 states.

Figure 3: Finite state machine representations of Tit for Tat. Finite state machine consist of a set of internal states. In (a) Tit for Tat finite state machine consists of 1 state and in (b) of 2. A machine also consists of transitions arrows associated with the states. Each arrow is labelled with A/R where A is the opponent's last action and R is the player's response.

To allow for easier identification of similar strategies [14] introduced a method called fingerprinting. The method of fingerprinting is a technique for generating a functional signature for a strategy [15]. This is achieved by computing the score of a strategy against a spectrum of opponents. The basic method is to play the strategy against a probe strategy with varying noise parameters. In [14] Tit for Tat is used as the probe strategy. In Figure 4 an example of Pavlov's fingerprint is given. Fingerprinting has been studied in depth in [15, 16, 17, 18].

This section covered structured strategies and training methods. In the following section software that has been developed with main aim simulating the iterated prisoner's dilemma is presented.

2.5 Software

The research of the iterated prisoner's dilemma heavily relays on software. This is to be expected as the pioneer computer tournaments have become the main mean of simulating the interactions in an iterated prisoner's dilemma game. Many academics fields suffer from the lack of source code availability and the prisoner's dilemma is not an exception. Though several of the tournaments that have been discussed so far were generated using computer code not all of the source code was made available by the authors. The code for Axelrod's original tournament is known to be lost and moreover for the second tournament the only source code available is the code for the 62 strategies (found on Axelrod's personal website [1]).

Several projects, however, are open, available and have been used as research tools or educational platforms over the years. Two research tools are briefly mentioned here [4, 9] and two educational tools [2, 3]. Both [4, 9] are

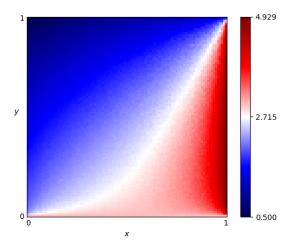

Figure 4: Pavlov fingerprinting with Tit for Tat used as the probe strategy. Figure was generated using [9].

open source projects used as research tools. PRISON is written in the programming language Java and preliminary version was launched on 1998. It was used by it's authors in several publications, such as [29] which introduced Gradual and [30]. The project includes a good number of strategies from the literature but unfortunately the last update of the project dates back in 2004. Axelrod-Python is a package used by [52, 64, 48, 117]. It is written in the programming language Python following best practice approaches and contains the largest collection of strategies, known to the author. The strategy list of the project has been cited by publications [12, 55, 87].

The 'Game of Trust' [2] is an on-line, graphical user interface educational platform for learning the basics of game theory, the iterated prisoner's dilemma and the notion of strategies. It attracted a lot of attention due to being "well-presented with scribble-y hand drawn characters" [56] and "a whole heap of fun" [62]. Finally [3] is a personal project written in PHP. It's graphical user interface that offers a big collection of strategies and allows the user to try several matches and tournament configurations.

2.6 Conclusion and Contemporary period

This section of the paper served as a review of publications on the prisoner's dilemma. This review has partitioned the literature into five different sections, focusing on different aspects of the research. Section 2.1 covered the early years of research. This was when simulating turns of the game was only possible with human subject research.

Following the early years, the pioneer tournaments of Axelord were introduced in Section 2.2. Axelord's work offered the field an agent based game theoretic framework to study the iterated prisoner's dilemma. In his original papers he asked researchers to design strategies to test their performance with the new framework. The winning strategy of both his tournaments was Tit for Tat. The strategy however came with limitations which were explored by other researchers and new strategies of intelligent design were introduced in order to surpass Tit for Tat with some contributions such as Pavlov and Gradual.

Soon researchers came to realise that strategies should not just do well in a tournament setting but should also be evolutionary robust. Evolutionary dynamics methods were applied to many works in the fields, and factors under which cooperation emerges were explored, as described in Section 2.3. This was not done only for unstructured populations, where all strategies in the population interacted with each other, but also in population where interactions were limited to only strategies that were close to each other. In such topologies it was proven that even in the one shot game cooperation can indeed emerge.

Evolutionary approaches can offer many insights in the study of the prisoner's dilemma. In evolutionary settings strategies can learn to adapt and take over population by adjusting their actions; Such algorithms can be applied so that evolutionary robust strategies can emerge. Algorithms and structures used to train strategies in the literature were covered in Section 2.4. Several strategies can emerge from such processes, and to be able to differentiate between strategies fingerprinting was introduced. The research of best play and cooperation has been going on since the 1950s, and software has been developed along the way. Few have been briefly discussed in Section 2.5.

The study of the prisoner's dilemma is still an ongoing field of pioneer and innovating research, where new variants and new structures of strategies are continuously being explored [93]. The game now serves as a model in a wide range of applications, for example in medicine and the study of cancer cells [13, 61], as well as in social situations and how they can be driven by rewards [41]. A lot of work is still being published on evolutionarily dynamics on graphs [10, 54, 71].

A large scale of articles has been covered in each of the corresponding sections of this review. This literature doe not pretend to have covered all the publications in the field. It will soon in the following section that the field has hab many publications, exceeding 3000 articles. However, several important milestones of the field have been presented here.

3 Analysing a large corpus of articles

The focus of Section 2 has been to review academic publications on the topic of the iterated prisoner's dilemma. Whilst in Section 2 several publications of specific interest were covered and the literature was manually partitioned in different sections, in the second part of this paper the publications are analysed using a large dataset of articles.

In Section 3.1 some background research on bibliometrics is discussed. The data collection process is covered in Section 3.2 and a preliminary analysis of the data is conducted in Section 3.3. In Section 3.4, the methodology which will be used to analyse the author relationships is presented, that is graph theoretical methods used to ascertain the level of collaborative nature of the field and identify influence. This type of analysis has been carried out in [70]. The novelty here is to consider approaches not considered in [70] such as the centrality measures of the network, and apply them to a new dataset. A further comparison of the results are made, relative to two other sub fields of game theory: auction games [79] and the price of anarchy [102] and a temporal analysis. Finally in Section 3.5, the results of the analysis are presented.

3.1 Background

As discussed in [121], bibliometrics (the statistical analysis of published works originally described by [95]) has been used to support historical assumptions about the development of fields [97], identify connections between scientific growth and policy changes [37], develop a quantitative understanding of author order [103], and investigate the collaborative structure of an interdisciplinary field [70]. Most academic research is undertaken in the form of collaborative effort and as [66] points out, it is rational that two or more people have the potential to do better as a group than individually. Collaboration in groups has a long tradition in experimental sciences and it has be proven to be productive according to [43]. The number of collaborations can be very different between research fields and understanding how collaborative a field is is not always an easy task. Several studies tend to consider academic citations as a measure for these things. A blog post published by Nature [89] argues that depending on citations can often be misleading because the true number of citations can not be known. Citations can be missed due to data entry errors, academics are influenced by many more papers than they actually cite and several of the citations are superficial.

A more recent approach to measure collaborative behaviour is to use the co authorship network, as described in [70]. Using this approach has many advantages as several graph theoretic measures can be used as proxies to explain authors relationship. In [70], they analyse the development of the field "evolution of cooperation"

using this approach. The topic "evolution of cooperation" is a multidisciplinary field which also includes a large number of publications on the prisoner's dilemma. This paper builds upon the work done by [70] and extends their methodology. Though in [70], they considered a data set from a single source, Web of Science, the data set described here has been collected from five different sources. Moreover, the collaborative results of the analysis are compared to those of two different sub fields.

Co authorship networks have also been used in [121] for classifying topics of an interdisciplinary field. This was done using centrality measures, which will be covered in Section 3.2, here centrality measures are used in order to understand the influence an author can have and can receive by being part of an academic group. Furthermore, in [11] they look at the relationship between research impact and five classes of diversity: ethnicity, discipline, gender, affiliation, and academic age. These characteristics of the authors are not being captured here. In future work these characteristics would be included in the analysis.

3.2 Data Collection

Academic articles are accessible through scholarly databases. Several databases and collections today offer access through an open application protocol interface (API). An API allows users to query directly a journal's database and bypass the graphical user interface. Interacting with an API has two phases: requesting and receiving. The request phase includes composing a url with the details of the request. For example, http://export.arxiv.org/api/query?search_query=abs:prisoner'sdilemma&max_results=1 represents a request message. The first part of the request is the address of the API. In this example the address corresponds to the API of arXiv. The second part of the request contains the search arguments. In this example it is requested that the word 'prisoners dilemma' exists within the article's title. The format of the request message is different from API to API. The receive phase includes receiving a number of raw metadata of articles that satisfies the request message. The raw metadata are commonly received in extensive markup language (xml) or Javascript object notation (json) formats [92]. Similarly to the request message, the structure of the received data differs from journal to journal.

The data collection is crucial to this study. To ensure that this study can be reproduced all code used to query the different APIs has been packaged as a Python library and is available online [88]. The software could be used for any type of projects similar to the one described here, documentation for it is available at: http://arcas.readthedocs.io/en/latest/. Project [88] allow users to collect articles from a list of APIs by specifying just a single keyword. Four prominent journals in the field and a pre print server were used as sources to collect data for this analysis: PLOS, Nature, IEEE, Springer and arXiv.

The following series of search terms were used to identify relevant articles:

- "prisoner's dilemma",
- "prisoners dilemma",
- "prisoner dilemma",
- "prisoners evolution",
- "prisoner game theory"

and articles for which any of these terms existed within the title, the abstract or the text are included in the analysis. More specifically, 23% of article considered here were included because any of the above terms existed within the abstract, 50% within the main text and 27% within the title. As will be described in Section 3.3, two other game theoretic sub fields auction games and the price of anarchy were also considered in this work. For collecting data on these sub fields the search terms used were "auction game theory" and "price of anarchy". The three data sets are archived and available at [6, 7, 8]. Note that the latest data collection was performed on 30thNovember 2018.

3.3 Preliminary Analysis

A summary of each of the three data sets used is presented in this section. The three data sets are:

- The main data set which contains articles on the prisoner's dilemma [8].
- A data set which contains article on auction games [6].
- A data set which contains articles on the price of anarchy [7].

The main data set is archived at [8]. It consists of 3089 articles with unique titles. In case of duplicates the preprint version of an article (collected from arXiv) was dropped. Of these 3089 article, 89 have not been collected from the aforementioned APIs. These articles were of specific interest and manually added to the dataset throughout the writing of Section 2. A similar approach was used in [70] where a number of articles of interest where manually added to the data set. A more detailed summary of the articles' provenance is given by Table 1. Only 3% of the data set consists of articles that were manually added and 34% of the articles were collected from arXiv.

	# of Articles	Percentage%
provenance		
Manual	89	2.88%
IEEE	295	9.55%
PLOS	482	15.60%
Springer	572	18.52%
Nature	673	21.79%
arXiv	1056	34.19%

Table 1: Articles' provenance for the main data set [8].

The average number of publications was calculated for the entire dataset and for each provenance. The average number of publications is denoted as, $\mu_P = \frac{N_A}{N_Y}$, where N_A is the total number of articles and N_Y is the years of publication. The years of publication is calculated as the range between the collection date and the first published article, for each provenance, within the data. These averages are summarised in Table 2. Overall an average of 49 articles are published per year on the topic. The most significant contribution to this appears to be from arXiv with 16 articles per year, followed by Nature with 10 and Springer with 9.

	Average Yearly publication
IEEE	5.0
PLOS	8.0
Springer	9.0
Nature	11.0
arXiv	16.0
Overall	49.0

Table 2: Average yearly publication (μ_P) for main data set [8].

Though the average publication offers insights about the publications of the fields, it remains a constant number. The data handled here is a time series from 1950, when the game was introduced, until 2018 (Figure 5). Two observations can be made from Figure 5.

1. There is a steady increase to the number of publications since the 1980s and the introduction of computer tournaments.

2. There is a decrease in 2017-2018. This is due to our data set being incomplete. Articles that have been written in 2017-2018 have either not being published or are not retrievable by the APIs yet.

These observations can be confirmed by studying the time series. Using [59], an exponential distribution is fitted to the data from 1980-2016. The exponential fit demonstrates that since 1980 there has been an increase in the number of publications until 2016 (Figure 6). The fitted model can also be used to forecast the behaviour of the field for the next 5 years. The forecasted periods are plotted in Figure 7. The time series has indicated a slight decrease however the model forecasts that the number of publications will keep increasing, thus indicating that the field of the iterated prisoner's dilemma still attracts academic attention.

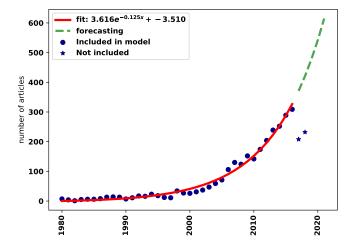

Figure 7: Forecast for 2017-2022.

To allow for a comparative analysis two sub fields of game theory have been chosen for this work; auction games and the price of anarchy.

- Auction theory is a branch of game theory which researches the properties of auction markets. Game theory has been used for years to study auctions and the behaviour of bidders [106]. The earliest entry in our data set [6] goes back to 1974 (Figure 8). Note that no articles have been added manually for auction games.
- Price of Anarchy is a concept in game theory which measures how the efficiency of a system degrades due to selfish behaviour of it's agents. There is a variety of such measures however the price of anarchy has attracted

a lot of attention since it's informal introduction in 1999 by [65]. Note that [65] has been manually added to the date set [7] and it's the first entry (Figure 9).

A summary of both data sets, in comparison to that of [8], is given by Table 3.

	Num. Articles	Num. Authors	Manual (%)	PLOS (%)	Nature (%)	Springer $(\%)$	IEEE (%)	arXiv $(\%)$	Av. Yearly Publication
Prisoner's Dilemma	3089	5811	2.88	15.6	21.79	18.52	9.55	34.19	49.0
Auction Games	3444	5362	-	-	5.89	37.63	7.46	51.36	93.0
Price of Anarchy	747	1315	0.13	1.74	24.63	38.02	30.66	8.84	39.0

Table 3: Measures of all three data sets.

The iterated prisoner's dilemma and auction theory are popular topics and have been studied for decades. A large number of articles have been collected for both topics, 3089 and 34444 respectively. Though, auction games have a larger number of articles, the iterated prisoner's dilemma has almost 300 more authors.

Auction games have an overall average yearly publication of 93 articles per year compared to the prisoner's dilemma with 49 per year. 50% of articles for auction games have been collected from the pre print server arXiv and no articles have been published in PLOS.

Compared to these two topics the price of anarchy is a fairly recent one. Only a total of 747 articles have been collected, however it has a large number of 1229 authors. On average each paper has two authors. It has an overall average yearly publication rate of 39 articles and the biggest contribution has been made to Springer (37%).

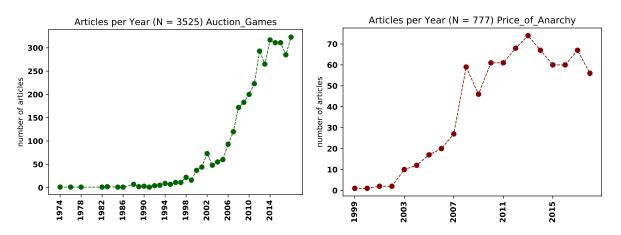

Figure 8: Line plot; # articles published on auction Figure 9: Line plot; # articles published on the price games 1974-2018.

3.4 Methodology

The relationship between the authors within a field will be modelled as a graph $G = (V_G, E_G)$ where V_G is the set of nodes and E_G is the setof edges. The set V_G represents the authors and an edge connects two authors if and only if those authors have written together. The co authorship network is constructed using the main data set described in Section 3.3 and the open source package [50]. The prisoner's dilemma network is denoted as G_1 where the number of unique authors $|V(G_1)|$ is 5811 and $|E(G_1)|$ is 10397. All authors' names were formatted as their last name and first initial (i.e. Martin A. Nowak to Martin Nowak). This was done to avoid errors such as Martin A. Nowak and Martin Nowak, being treated as a different person.

Collaborativeness, will be analysed using measures such as, isolated nodes, connected components, clustering coefficient, communities, modularity and average degree. These measures show the number of connections authors can

have and how strongly connected these people are. The number of isolated nodes is the number of nodes that are not connected to another node, thus the number of authors that have published alone. The average degree denotes the average number of neighbours for each nodes, i.e. the average number of collaborations between the authors.

A connected component is a maximal set of nodes such that each pair of nodes is connected by a path. The number of connected components as well as the size of the largest connected component in the network are reported. The size of the largest connected component represents the scale of the central cluster of the entire network, as it will discussed in the analysis section. Clustering coefficient and modularity and are also calculated. The clustering coefficient, defined as 3 times the number of triangle on the graph divided by the number of connected triples of nodes, is a local measure of the degree to which nodes in a graph tend to cluster together in a clique. It is precisely the probability that the collaborators of an author also write together.

In comparison, modularity is a global measure designed to measure the strength of division of a network into communities. The number of communities will be reported using the Clauset-Newman-Moore method [36]. Also the modularity index is calculated using the Louvain method described in [32]. The value of the modularity index can vary between [-1,1], a high value of modularity corresponds to a structure where there are dense connections between the nodes within communities but sparse connections between nodes in different communities. That means that authors in the network are mainly connected co-authors that they all have written together, and not to several different collaborators.

Networks are commonly dominated by one person who controls information flow and people that receive a great amount of information due to their position. Two further points are aimed to be explored in this work, (1) which people control the flow; as in which people influence the field the most and (2) which are the authors that gain the most from the influence of the field. To measure these concepts graph theoretic metrics, more specifically centrality measures are going to be used. Centrality measures are often used to understand different aspects fo social networks [67]. Two centrality measures have been chosen for this paper and these are closeness and betweenness centrality.

- 1. In networks some nodes have a short distance to a lot of nodes and consequently are able to spread information on the network very effectively. A representative of this idea is **closeness centrality**, where a node is seen as centrally involved in the network if it requires only few intermediaries to contact others and thus is structurally relatively independent. Here, this is interpreted as influence. Authors with a high value of closeness centrality, are the authors that spread scientific knowledge easier on the network and they have high influence.
- 2. Another centrality measure is the **betweenness centrality**, where the determination of an author's centrality is based on the quotient of the number of all shortest paths between nodes in the network that include the node in question and the number of all shortest paths in the network. In betweenness centrality the position of the node matters. Nodes with a higher value of betweenness centrality are located in positions that a lot of information pass through them, this is interpreted as the gain from the influence, thus these authors gain the most from their networks.

In the next section all the metrics discussed here are calculated for the data sets in order to provide insights into the field.

3.5 Analysis of co authorship network

As mentioned previously, G_1 denotes the co authorship network of the iterated prisoner's dilemma. A graphical representation is given by Figure 10a. It is evident that the network is disjoint, which is only natural as many authors write academic articles on their own. More specifically, a total of 176 authors, have had single author publications, which corresponds to the 3.3 (%) of authors in G_1 .

There are a total of 1356 connected components and the largest one has a size of 815 nodes. The largest connected component is shown in Figure 10b and is going to be referred to as the main cluster of the network. There are

total of 1369 communities in G_1 . The network has a clustering coefficient of 0.708, thus authors are 70% likely to write with a collaborator's co author and the degree distribution, Figure 11, shows that the average degree is approximately 4. Thus authors are on average connected to 4 other authors, however there are authors with far more connections, the largest one being 58.

In [70] the collaborative metrics for the "evolution of cooperation" co authorship network were reported. Though their network is of smaller size (number of nodes 3670 < 5394), the collaborative metrics are fairly similar between the two graphs (clustering coeff. 0.632 and modularity 0.950 close to 0.977, indicating that for the same multidisciplinary field the same remarks can be made from a different co authors network. How do these compare to other fields and more specifically to other fields of game theory?

The auction games network G_2 , and the price of anarchy network G_3 are given by Figures 10c and 10e and their respective largest cluster in Figures 10d and 10f. As stated before G_3 is the smallest network. G_2 network appears to be very similar to G_1 , however it's main cluster is larger in size.

A summary of the collaborative metrics for all three co authorship networks is given by Table 4 and the degree distribution of all three networks is shown in Figure 11.

	# Nodes	# Edges	# Isolated nodes	% Isolated nodes	# Connected components	Size of largest component	Av. degree	# Communities	Modularity	Clustering coeff
Prisoner's Dilemma	5394	10397	176	3.3	1356	815	3.855	1369	0.978	0.708
Auction Games	5165	7861	256	5.0	1272	1348	3.044	1297	0.957	0.622
Price of Anarchy	1155	1953	4	0.3	245	222	3.382	253	0.964	0.712

Table 4: Network metrics for G_1, G_2, G_3 .

Using Table 4 and Figure 11 the following remarks can be made:

- All three networks have similar values of modularity index, and they are all very high (Table 4), indicating that the networks are partitioned in many communities. Note that the number of communities is very much similar to the number of connected components. This is all to expected. Due to the nature of our network, most connected components represent a single publication written by all the authors in the component (corresponding to a fully connected graph), and due to that density they are also a community on their own.
- Comparing to another well studied topic, auction games, the field of the iterated prisoner's dilemma appears to be more collaborative. Due to the value of the average degree, authors in G_1 are known to have on average almost one more collaboration than G_2 . A slightly lower cluster coefficient (.622 < .702) of auction games indicate that it is less likely for authors in G_2 to collaborate with a co author.
- Regarding the price of anarchy, the measures indicate that the field is not as mature as the other two sub fields. There are no isolated authors, which is more of an indication of the time the field has been active. As a more recent field there had been better communication tools that enable more collaborations between researches. The average degree as well as the clustering coefficient (clustering coeff.= 0.713) of G_3 is comparable to those of the iterated prisoner's dilemma.

These results can be extended to the main clusters of each network, as shown in Table 5. The metrics's values are fairly similar and the size of G_2 's main cluster does not appear to gave any significant effect; all the same conclusions are made.

	# Nodes	# Edges	# Isolated nodes	% Isolated nodes	# Connected components	Size of largest component	Av. degree	# Communities	Modularity	Clustering coeff
Prisoner's Dilemma	815	2300	0	0.0	1	815	5.644	28	0.856	0.775
Auction Games	1348	3158	0	0.0	1	1348	4.685	29	0.859	0.699
Price of Anarchy	222	521	0	0.0	1	222	4.694	12	0.824	0.711

Table 5: Network metrics for largest components of G_1, G_2, G_3 .

The change of the networks over time is also studied by constructing the network cumulatively using a year interval. A total of 64 sub graphs over 64 periods, starting in 1950, were created and all the collaborative metrics for each

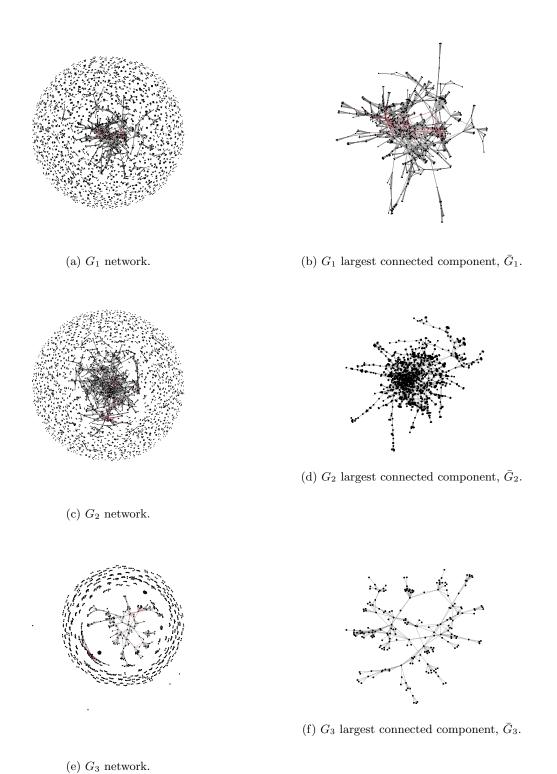

Figure 10: Graphical representations of G_1, G_2, G_3 and their respective main clusters.

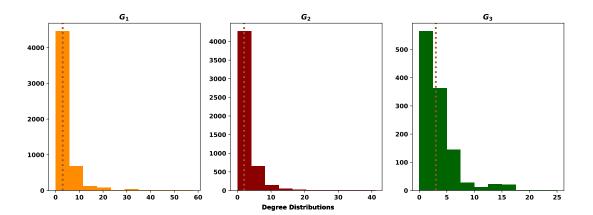

Figure 11: Degree distribution for networks G_1 , G_2 and G_3 . The descriptive statistics for each of the distribution are for G_1 : mean = 3.85, median = 3, std = 4.25. For G_2 : mean = 3.04, median = 2, std = 3.01 and for G_3 : mean = 3.38, median = 3, std = 2.90. It is clear that these distributions are not normally distributed, which has also been verified using a statistical test. Moreover, the statistical difference of the medians has been tested using a Kruskal Wallis test. The medians of G_1 and G_3 are not significantly different, however they are are significantly large than that of G_2 .

sub graph have been calculated. Note that years 1952 and 1953 have no publications in our data set. The metrics of each network for each period are given by Table 6. Similar to the results of [70], it can been observed that the network G_1 grows over time and that the network always had a high value of modularity.

To better assess the change over time for each metric they have been plotted in Figure 12. The number of nodes, connected components and the size of largest component have been normalised such that the trend between the three networks can be compared.

- In Figure 12a the normalised number of nodes, which is calculated by dividing by the total number of nodes in each respective network, is shown. A steep increase in the size of all three networks is spotted soon after 2000. This could indicate that more data have been available in the sources used in this work following the year 2000. It is however, definitely not a effect of a single field, as it is true for all three sub fields considered here. The sudden increase following the year 2000, is also reported by the number of connected components and the size of the main cluster, Figures 12c, 12d. A connected components represents at least one publication which means that indeed more articles are being gathered from 2000 onwards.
- Auction games have been throughout of time less collaborative compared to the iterated prisoner's dilemma. The average degree (Figure 12b) and the clustering coefficient (Figure 12e) of the cumulative sub graphs have been lower than that of G_1 . The only exception is during the years 2001-2008. For these year auction games appear to have had a more collaborative environment.
- In the price of anarchy cumulative graphs a sharp increase since the beginning of the field can be observed for all metrics. There are not many data points due to the recent development of the field, however these steep trends could be an indication that game theoretic and potentially all scientific research has over time been more collaborative. This could be due to logistic and technical solutions.
- The high values of modularity throughout time is not true only for the network reported in [70] but also for all three networks of this field. This could indicate a limitation to the co authorship network. The measure is likely to be skewed, as each paper is more likely a connected component on it's own.

The cumulative collaborative metrics have also been calculated for each main cluster, given in Table 7. Similarly, the results do not appear to change over the main cluster.

1951 1955 22	-	# Nodes	# Edges	# Isolated nodes	% Isolated nodes	# Connected components	Size of largest component	Av. degree	# Communities	Modularity	Clustering coeff

Table 7: Collaborativeness metrics for cumulative graphs' main clusters, $G\subseteq \bar{G}_1$.

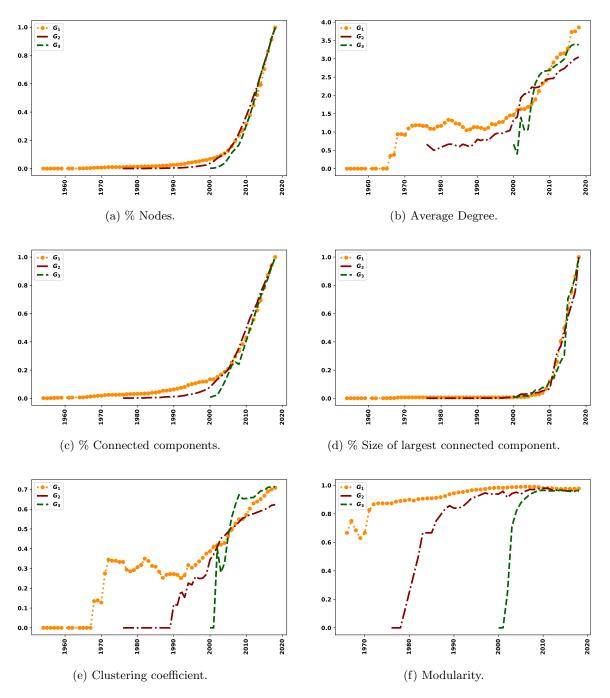

Figure 12: Collaborative metrics over time for cumulative networks for $G_1,\,G_2$ and $G_3.$

The next results discussed here are on centrality measures. As a reminder, two centrality measures are reported here, these are the closeness centrality and the betweenness centrality. Closeness centrality is a measure of how easy is for an author to contact others, and consequently affect them; influence them. Thus closeness centrality here is a measure of influence. Betweenness centrality is a measure of how many paths pass through a specific node, thus the amount of information this person has access to. Betweenness centrality is used here as a measure of how much an author gain from the field. All centrality measure can have values ranging from [0, 1].

For G_1 the most central author based on closeness and betweenness are given by Tables 13 and 14 respectively. The betweenness centrality of the most central authors in G_1 are rather low with the highest ranked author being Matjaz Perc with a between centrality of 0.008, Table 14. A publication of Perc's work has been briefly discussed in Section, and the centrality measure suggest that the network is influenced by him. He is connected to a total of 58 nodes and he has published to all five of the different sources considered in the study. Though he also gains from his position in the network, the gain is minor. An author who is not in the top influencers but does indeed gain from his position in the network is Martin Nowak, who was extensively discussed in Section 2.

	Name	Closeness
1	Matjaz Perc	0.048447
2	Yamir Moreno	0.044840
3	Zhen Wang	0.044005
4	Long Wang	0.043770
5	Attila Szolnoki	0.043338
6	Luo-Luo Jiang	0.042148
7	Arne Traulsen	0.041790
8	Valerio Capraro	0.041257
9	Cheng-Yi Xia	0.040791
10	Angel Sanchez	0.040562

	Name	Betweeness
1	Matjaz Perc	0.008331
2	Zhen Wang	0.006356
3	Yamir Moreno	0.004806
4	Long Wang	0.003538
5	Martin Nowak	0.003230
6	Valerio Capraro	0.002739
7	Arne Traulsen	0.002479
8	Angel Sanchez	0.002319
9	Jianye Hao	0.002188
10	Franz Weissing	0.002186

Figure 13: Ten most influenced authors in G_1 .

Figure 14: Authors that gain the most influence in G_1 .

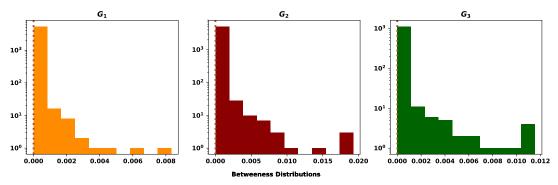

From Tables 13 and 14 it can be seen that authors in G_1 are more likely to affect their field instead of gaining from it. This can be better explored by considering the distributions of the centralities and by comparing them to other fields. The distributions for both centralities are plotted in Figures 15a and 16a, and in Figures 15b and 16b for their respective main clusters.

Regarding gaining from your network. An author is more likely to gain more from the influence of the field if they were authors in auction games or the price of anarchy. Though if it were an author in the main cluster it would make to statistical difference in which field they were to published. Overall, all the betweenness values are rather small and the distributions skewed to the left. This could imply that in all three networks, authors do not gain much from the influence of their fields.

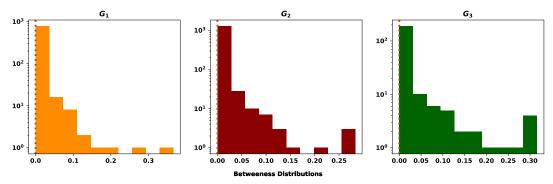

In relation to influencing your field. An author is most likely to influence their field if they write for the price of anarchy and authors that publish on auctions game are more likely to influence compared to authors in the iterated prisoner's dilemma. Though if an author was to be placed in the main cluster of the respective field they would chose to be in either G_1 or G_3 . In conclusion, authors regarding both influence metrics that have been defined here are more likely to gain more if they were to published on either topics of auction games or the price of anarchy. Though the value of gaining is actual small, you are more likely to influence your field more in another field compared to that of the prisoner's dilemma.

4 Acknowledgements

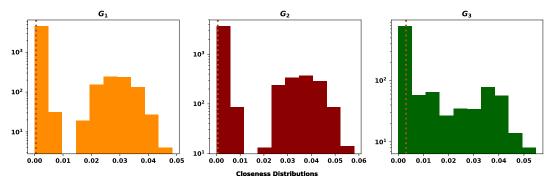

A variety of software libraries have been used in this work:

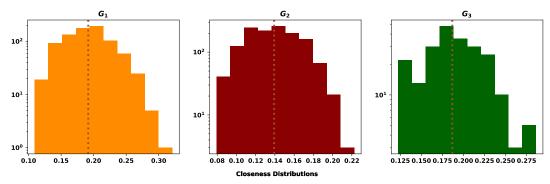

(a) Betweenness centrality distributions G_1, G_2, G_3 . The descriptive statistics for each of the distribution are for G_1 : mean= 0.000019, median= 0.0, std= 0.000207. For G_2 : mean= 0.000086, median= 0.0, std= 0.000693 and for G_3 : mean= 0.000151, median= 0.0, std= 0.000931. None of the three distributions is normally distributed and there is significant difference between the means (these have been tested using appropriate statistical difference). According to a Mann Whitney both G_2 and G_3 medians are significant larger than that of G_1 however there is not statistical difference between those two medians.

(b) Betweenness centrality distributions for G_1, G_2, G_3 respective main clusters. The descriptive statistics for each of the distribution are for G_1 : mean= 0.0054, median= 0.0, std= 0.022. For G_2 : mean= 0.0048, median= 0.0, std= 0.019 and for G_3 : mean= 0.02, median= 0.0, std= 0.055. None of the three distributions is normally distributed. There is no statistical difference between the median of G_2 . These have been tested using a Kruskal Wallis test.

(a) Closeness centrality distributions G_1, G_2, G_3 . The descriptive statistics for each of the distribution are for G_1 : mean= 0.0050, median= 0.00056, std= 0.010. For G_2 : mean= 0.00086, median= 0.00058, std= 0.000693 and for G_3 : mean= 0.000151, median= 0, std= 0.000931. None of the three distributions is normally distributed and the median of G_3 is statistically larger than that of G_2 , which is larger than that of G_1 .

(b) Closeness centrality distributions for G_1, G_2, G_3 respective main clusters. The descriptive statistics for each of the distribution are for G_1 : mean= 0.19, median= 0.19, std= 0.035. For G_2 : mean= 0.14, median= 0.14, std= 0.026 and for G_3 : mean= 0.19, median= 0.19, std= 0.035. None of the three distributions is normally distributed. All medians are statistically different. The medians of G_1 and G_3 are greater than that of G_2 .
